

Package ‘modi’

September 27, 2016

Type Package

Title Multivariate outlier detection and imputation for incomplete survey data

Version 1.6

Date 2015-10-30

Author Beat Hulliger

Maintainer Beat Hulliger <beat.hulliger@fhnw.ch>

Description Algorithms for multivariate outlier detection when missing values occur. Algorithms are based on Mahalanobis distance or data depth. Imputation is based on the multivariate normal model or uses nearest neighbour donors. The algorithms take sample designs, in particular weighting, into account.

 modi-package

Multivariate outlier detection for incomplete survey data

Description

The package `modi` is a collection of functions for multivariate outlier detection and imputation. The aim is to provide a set of functions which cope with missing values and take sampling weights into account. The original functions were developed in the EUREDIT project. This work was partially supported by the EU FP5 ICT programme, the Swiss Federal Office of Education and Science and the Swiss Federal Statistical Office. Subsequent development was in the AMELI project of the EU FP7 SSH Programme and also supported by the University of Applied Sciences and Arts Northwestern Switzerland (FHNW).

 BEM

BACON-EEM Algorithm for multivariate outlier detection in incomplete multivariate survey data

Description

BEM starts from a set of uncontaminated data with possible missing values, applies a version of the EM-algorithm to estimate the center and scatter of the good data, then adds (or deletes) observations to the good data which have a Mahalanobis distance below a threshold. This process iterates until the good data remain stable. Observations not among the good data are outliers.

Usage

```
BEM(data, weights, v = 2, c0 = 3, alpha = 0.01, md.type = "m",
em.steps.start = 10, em.steps.loop = 5, better.estimation = FALSE, monitor = FALSE)
```

Arguments

<code>data</code>	a matrix or data frame. As usual, rows are observations and columns are variables.
<code>weights</code>	a non-negative and non-zero vector of weights for each observation. Its length must equal the number of rows of the data. Default is <code>rep(1, nrow(data))</code> .
<code>v</code>	an integer indicating the distance for the definition of the starting good subset: <code>v=1</code> uses the Mahalanobis distance based on the weighted mean and covariance, <code>v=2</code> uses the Euclidean distance from the componentwise median
<code>c0</code>	the size of initial subset is <code>c0*ncol(data)</code> .
<code>alpha</code>	a small probability indicating the level $(1-\alpha)$ of the cutoff quantile for good observations
<code>md.type</code>	Type of Mahalanobis distance: "m" marginal, "c" conditional
<code>em.steps.start</code>	Number of iterations of EM-algorithm for starting good subset
<code>em.steps.loop</code>	Number of iterations of EM-algorithm for good subset
<code>better.estimation</code>	If <code>better.estimation=TRUE</code> then the EM-algorithm for the final good subset iterates <code>em.steps.start</code> more.
<code>monitor</code>	If <code>TRUE</code> verbose output.

Details

The BACON algorithm with `v=1` is not robust but affine equivariant while `v=2` is robust but not affine equivariant. The threshold for the (squared) Mahalanobis distances, beyond which an observation is an outlier, is a standardised chisquare quantile at $(1-\alpha)$. For large data sets it may be better to choose α/n instead.

The internal function `.EM.normal` is usually called from `BEM`. `.EM.normal` is implementing the EM-algorithm in such a way that part of the calculations can be saved to be reused in the `BEM` algorithm. `.EM.normal` does not contain the computation of the observed sufficient statistics, they will be computed in the main program of `BEM` and passed as parameters as well as the statistics on the missingness patterns.

Value

`BEM` returns a list whose first component is the sub-list output with the following components:

<code>sample.size</code>	number of observations
<code>discarded.observations</code>	Number of discarded observations
<code>number.of.variables</code>	Number of variables
<code>significance.level</code>	the probability used for the cutpoint, i.e. α
<code>initial.basic.subset.size</code>	Size of initial good subset

```

final.basic.subset.size      Size of final good subset
number.of.iterations        Number of iterations of the BACON step
computation.time            Elapsed computation time
center                      Final estimate of the center
scatter                     Final estimate of the covariance matrix
cutpoint                    The threshold MD-value for the cut-off of outliers

The further components returned by BEM are:

outind                      Outlier indicator
dist                        Final Mahalanobis distances

```

Note

BEM uses an adapted version of the EM-algorithm in funktion EM-normal.

Examples

```

# Bushfire data set with 20% MCAR
data(bushfire,bushfire.weights)
bem.res<-BEM(bushfire,bushfire.weights,alpha=(1-0.01/nrow(bushfire)))
print(bem.res$output)

```

bushfire

Bushfire scars

Description

The bushfire data set was used by Campbell (1984, 1989) to locate bushfire scars. The dataset contains satellite measurements on five frequency bands, corresponding to each of 38 pixels.

Usage

```
data(bushfire)
```

Format

A data frame with 38 observations on 5 variables.

Details

The data contains an outlying cluster of observations 33 to 38 a second outlier cluster of observations 7 to 11 and a few more isolated outliers, namely observations 12, 13, 31 and 32. bushfirem is created from bushfire by setting a proportion of 0.2 of the values to missing.

Source

```
bushfirem: set.seed(234567891) miss.rate <- 0.2 miss.ind<-rep(F,n*p) miss.ind[sample(n*p,floor(miss.rate*n*p))]
bushmiss<-matrix(miss.ind,ncol=5) mean(bushmiss) bushfirem<-bushfire bushfirem[bushmiss]<-NA
```

For testing purposes weights are provided: bushfire.weights<-rep(c(1,2,5),length=nrow(bushfire))

References

Campbell, N. (1989) Bushfire mapping using noaa avhrr data. Technical Report. Commonwealth Scientific and Industrial Research Organisation, North Ryde.

Examples

```
data(bushfire)
## maybe str(bushfire) ; plot(bushfire) ...
```

EAdet

Epidemic Algorithm for detection of multivariate outliers in incomplete survey data.

Description

In EAdet an epidemic is started at a center of the data. The epidemic spreads out and infects neighbouring points (probabilistically or deterministically). The last points infected are outliers. After running EAdet an imputation with EAimp may be run.

Usage

```
EAdet(data, weights, reach = "max", transmission.function = "root", power = ncol(data),
       distance.type = "euclidean",
       maxl = 5, plotting = TRUE, monitor = FALSE,
       prob.quantile = 0.9, random.start = FALSE, fix.start, threshold = FALSE,
       deterministic = TRUE, rm.missobs=FALSE,verbose=FALSE)
```

Arguments

<code>data</code>	a data frame or matrix with the data
<code>weights</code>	a vector of positive sampling weights
<code>reach</code>	if <code>reach="max"</code> the maximal nearest neighbour distance is used as the basis for the transmission function, otherwise the weighted $(1-(p+1)/n)$ quantile of the nearest neighbour distances is used.
<code>transmission.function</code>	form of the transmission function of distance <code>d</code> : "step" is a heaviside function which jumps to 1 at <code>d0</code> , "linear" is linear between 0 and <code>d0</code> , "power" is $(\text{beta} \cdot d + 1)^{-p}$ for <code>p=ncol(data)</code> as default, "root" is the function $1-(1-d/d0)^{(1/\text{maxl})}$
<code>power</code>	sets <code>p=power</code>
<code>distance.type</code>	distance type in function <code>dist()</code>
<code>maxl</code>	Maximum number of steps without infection
<code>plotting</code>	if TRUE the cdf of infection times is plotted
<code>monitor</code>	if TRUE verbose output on epidemic
<code>prob.quantile</code>	If mads fail take this quantile absolute deviation
<code>random.start</code>	If TRUE take a starting point at random instead of the spatial median
<code>fix.start</code>	Force epidemic to start at a specific observation
<code>threshold</code>	Infect all remaining points with infection probability above the threshold $1-0.5^{(1/\text{maxl})}$
<code>deterministic</code>	if TRUE the number of infections is the expected number and the infected observations are the ones with largest infection probabilities.
<code>rm.missobs</code>	Set <code>rm.missobs=TRUE</code> if completely missing observations should be discarded. This has to be done actively as a safeguard to avoid mismatches when imputing.
<code>verbose</code>	More output with <code>verbose=TRUE</code> .

Details

The form and parameters of the transmission function should be chosen such that the infection times have at least a range of 10. The default cutting point to decide on outliers is the median infection time plus three times the mad of infection times. A better cutpoint may be chosen by visual inspection of the cdf of infection times.

EAdet calls the function `EA.dist`, which passes the counterprobabilities of infection (an $n * (n - 1)/2$ size vector!) and three parameters (sample spatial median index, maximal distance to nearest neighbor and transmission distance=`reach`) as arguments to `EA.det`. The distances vector may be too large to be passed as arguments. Then either the memory size must be increased. Former versions of the code used a global variable to store the distances in order to save memory.

Value

EAdet returns a list whose first component output is a sub-list with the following components:

<code>sample.size</code>	Number of observations
<code>discarded.observations</code>	Indices of discarded observations
<code>missing.observations</code>	Indices of completely missing observations
<code>number.of.variables</code>	Number of variables

n.complete.records	Number of records without missing values
n.usable.records	Number of records with less than half of values missing (unusable observations are discarded)
medians	Component wise medians
mads	Component wise mads
prob.quantile	Use this quantile if mads fail, i.e. if one of the mads is 0.
quantile.deviations	Quantile of absolute deviations.
start	Starting observation
transmission.function	Input parameter
power	Input parameter
maxl	Maximum number of steps without infection
min.nn.dist	maximal nearest neighbor distance
transmission.distance	d0
threshold	Input parameter
distance.type	Input parameter
deterministic	Input parameter
number.infected	Number of infected observations
cutpoint	Cutpoint of infection times for outlier definition
number.outliers	Number of outliers
outliers	Indices of outliers
duration	Duration of epidemic
computation.time	Elapsed computation time
initialisation.computation.time	Elapsed computation time for standardisation and calculation of distance matrix

The further components returned by EAdet are:

infected	Indicator of infection
infection.time	Time of infection
outind	Indicator of outliers

See Also

[EAimp](#) for imputation with the Epidemic Algorithm.

Examples

```
data(bushfirem,bushfire.weights)
det.res<-EAdet(bushfirem,bushfire.weights)
print(det.res$output)
```

EAimp

Epidemic Algorithm for imputation of multivariate outliers in incomplete survey data.

Description

After running EAdet an imputation of the detected outliers with EAimp may be run.

Usage

```
EAimp(data, weights , outind, reach="max", transmission.function = "root",
power=ncol(data), distance.type = "euclidean",
duration = 5, maxl = 5,
kdon = 1, monitor = FALSE, threshold = FALSE,
deterministic = TRUE, fixedprop = 0)
```

Arguments

data	a data frame or matrix with the data
weights	a vector of positive sampling weights
outind	a logical vector with component TRUE for outliers
reach	reach of the threshold function (usually set to the maximum distance to a nearest neighbour, see internal function .EA.dist)
transmission.function	form of the transmission function of distance d: "step" is a heaviside function which jumps to 1 at d0, "linear" is linear between 0 and d0, "power" is $(\beta d + 1)^{-p}$ for $p = \text{ncol}(\text{data})$ as default, "root" is the function $1 - (1 - d/d0)^{(1/\text{maxl})}$
power	sets $p = \text{power}$, where p is the parameter in the above transmission function.
distance.type	distance type in function dist()
maxl	Maximum number of steps without infection
monitor	if TRUE verbose output on epidemic
threshold	Infect all remaining points with infection probability above the threshold $1 - 0.5^{(1/\text{maxl})}$
deterministic	if TRUE the number of infections is the expected number and the infected observations are the ones with largest infection probabilities.
duration	The duration of the detection epidemic
kdon	The number of donors that should be infected before imputation
fixedprop	If TRUE a fixed proportion of observations is infected at each step

Details

EAimp uses the distances calculated in EAdet (actually the counterprobabilities, which are stored in a global data set) and starts an epidemic at each observation to be imputed until donors for the missing values are infected. Then a donor is selected randomly.

Value

EAimp returns a list with components parameters and imputed.data.

parameters contains the following components:

sample.size	Number of observations
number.of.variables	Number of variables
n.complete.records	Number of records without missing values
n.usable.records	Number of records with less than half of values missing (unusable observations are discarded)
duration	Duration of epidemic
reach	Transmission distance (d0)
threshold	Input parameter
deterministic	Input parameter
computation.time	Elapsed computation time

imputed.data contains the imputed data.

Examples

```
data(bushfirem,bushfire.weights)
det.res<-EAdet(bushfirem,bushfire.weights)
imp.res<-EAimp(bushfirem,bushfire.weights,outind=det.res$outind,
reach=det.res$output$max.min.di,kdon=3)
print(imp.res$output)
```

ER

*Robust EM-algorithm ER***Description**

The ER function is an implementation of the ER-algorithm of Little and Smith (1987).

Usage

```
ER(data, weights, alpha = 0.01, psi.par = c(2, 1.25),
  em.steps = 100, steps.output = FALSE, Estep.output=FALSE, tolerance=1e-6)
```

Arguments

data	a data frame or matrix
weights	sampling weights
alpha	probability for the quantile of the cut-off
psi.par	further parameters passed to the psi-function
em.steps	number of iteration steps of the EM-algorithm
steps.output	if TRUE verbose output
Estep.output	if TRUE estimators are output at each iteration
tolerance	convergence criterion (relative change)

Details

The M-step of the EM-algorithm uses a one-step M-estimator.

Value

sample.size	number of observations
number.of.variables	Number of variables
significance.level	alpha
computation.time	Elapsed computation time
good.data	Indices of the data in the final good subset
outliers	Indices of the outliers
center	Final estimate of the center
scatter	Final estimate of the covariance matrix
dist	Final Mahalanobis distances
rob.weights	Robustness weights in the final EM step

data(bushfire.weights)
det.res<-ER(bushfirem, weights=bushfire.weights,alpha=0.05,steps.output=TRUE,em.steps=100,tol=2e-6)
PlotMD(det.res$dist,ncol(bushfirem))
```

GIMCD

Gaussian imputation followed by MCD

Description

Gaussian imputation uses the classical non-robust mean and covariance estimator and then imputes predictions under the multivariate normal model. Outliers may be created by this procedure. Then a high-breakdown robust estimate of the location and scatter with the Minimum Covariance Determinant algorithm is obtained and finally outliers are determined based on Mahalanobis distances based on the robust location and scatter.

Usage

```
GIMCD(data, alpha = 0.05, seedem, seedmcd)
```

Arguments

data	a data frame or matrix with the data
alpha	a threshold value for the cut-off for the outlier Mahalanobis distances
seedem	random number generator seed for EM algorithm, default is 234567819
seedmcd	random number generator seed for MCD algorithm, if seedmcd is missing an internal seed will be used.

Details

Normal imputation from package norm and MCD from package MASS. Note that currently MCD does not accept weights.

Value

Result is stored in a global list GIMCD.r:

center	robust center
scatter	robust covariance
alpha	Quantile for cut-off value

computation.time	Elapsed computation time
outind	logical vector of outlier indicators
dist	Mahalanobis distances

data(bushfirem)
det.res<-GIMCD(bushfirem,alpha=0.1)
print(det.res$center)
PlotMD(det.res$dist,ncol(bushfirem))
```

MDmiss

*Mahalanobis distance (MD) for data with missing values.***Description**

For each observation the missing dimensions are omitted before calculating the MD. The MD contains a correction factor p/q to account for the number of observed values, where p is the number of variables and q is the number of observed dimensions for the particular observation.

Usage

```
MDmiss(data, center, cov)
```

Arguments

data	The data as a data frame or matrix.
center	The center to be used (may not contain missing values).
cov	The covariance to be used (may not contain missing values).

Details

The function loops over the observations. This is not optimal if only a few missingness patterns occur. If no missing values occur the function returns the Mahalanobis distance.

Value

The function returns a vector of the (squared) Mahalanobis distances.

modi-internal	<i>Internal Functions of modi-package</i>
---------------	---

Description

The modi-package contains internal functions which are normally not called directly by the user. The internal functions are specifically built for the modi-package and are mainly used to improve efficiency and speed in the main functions of the package.

Calculation of distances for Epidemic Algorithm for multivariate outlier detection and imputation: `.EA.dist(data,n,p,weights,reach,transmission.function, power, distance.type, maxl)`

Non-zero non-missing minimum function: `.nz.min(x)`

Addressing function for Epidemic Algorithm: `.ind.dij(i, j, n)`

Addressing function for Epidemic Algorithm: `.ind.dijs(i, js, n)`

Sum of weights for observations < value (if lt=T) or observations=value (if lt=F): `.sum.weights(observations,weight`

Definition of the sweep and reverse-sweep operator: `.sweep.operator(M,k,reverse=FALSE)`

psi-function (defined in Little and Smith for ER algorithm): `.psi.lismi(d,present,psi.par=c(2,1.25))`

EM for multivariate normal data: `.EM.normal(data, weights=rep(1,nrow(data)), n=sum(weights) ,p=ncol(dat`

ER for multivariate normal data: `.ER.normal(data, weights=rep(1,nrow(data)), psi.par=c(2,1.25), np=sum(v`

Arguments

<code>data</code>	a data frame or matrix with the data
<code>n</code>	<code>nrow(data)</code>
<code>p</code>	<code>ncol(data)</code>
<code>weights</code>	a vector of positive sampling weights
<code>reach</code>	if <code>reach="max"</code> the maximal nearest neighbour distance is used as the basis for the transmission function, otherwise the weighted $(1 - (p + 1)/n)$ quantile of the nearest neighbour distances is used.

transmission.function	form of the transmission function of distance d: "step" is a heaviside function which jumps to 1 at d_0 , "linear" is linearly decreasing from 1 to 0 between 0 and d_0 , "power" is $(\beta * d + 1)^{-p}$ with $p = ncol(data)$ as default, "root" is the function $1 - (1 - d/d_0)^{1/maxl}$
power	sets $p=power$
maxl	Maximum number of steps without infection
monitor	if TRUE verbose output on epidemic
x	vector of numeric values
i	index for row
j	index for column
js	vector of indices of columns
observations	Number of observations
value	an integer, indicating the threshold for the sum of weights computation
lt	if TRUE, sum of weights for observations $< value$ is returned. If FALSE, sum of weights for observations $= value$ is returned
M	an array, including a matrix
k	a vector giving the subscripts which the function will be applied over. E.g., for a matrix 1 indicates rows, 2 indicates columns
reverse	logical value
s.counts	counts of the different missingness patterns ordered alphabetically
s.id	indices of the last observation of each missingness pattern in the dataset ordered by missingness pattern
S	total number of different missingness patterns
T.obs	Sufficient statistics on complete observations
start.mean	starting value for mean vector
start.var	starting value for variance vector
numb.it	number of iterations
Estep.output	logical, TRUE if verbose output is desired
psi.par	further parameters passed to the psi-function
np	population size
missing.items	Indices of missing items
nb.missing.items	number of missing items
tolerance	stop iterations when change is below tolerance

Details

.EA.dist creates a vector of length $n * (n - 1)/2$ in the global environment. To avoid memory problems this vector is not (!) passed as a function result.

Value

A list with two components: The first component output is a list with components

`sample.spatial.median.index`

The index of the observation with minimal sum of absolute distances to all other points

`max.min.di` The maximum distance to a nearest neighbour

`d0` The reach of the transmission function

The second component is

`min.dist2nn` A vector of the distances to the nearest neighbour

Author(s)

Cédric Béguin, Beat Hulliger

References

PlotMD

QQ-Plot of Mahalanobis distances

Description

QQ-plot of (squared) Mahalanobis distances vs. scaled F-distribution (or a scaled chisquare distribution). In addition two default cutpoints are proposed.

Usage

```
PlotMD(dist, p, alpha = 0.95, chisquare=FALSE)
```

Arguments

`dist` a vector of Mahalanobis distances

`p` the number of variables involved in the Mahalanobis distances

`alpha` a probability for cut-off, usually close to 1

`chisquare` A logical indicating the the chisquare distribution should be used instead of the F-distribution

Details

Scaling of the F-distribution as $median(dist) * qf((1 : n)/(n + 1), p, n - p) / qf(0.5, p, n - p)$. First default cutpoint is $median(dist) * qf(alpha, p, n - p) / qf(0.5, p, n - p)$ and second default cutpoint is the alpha-quantile of the Mahalanobis distances.

Value

hmed first proposed cutpoint based on F-distribution.
 halpha second proposed cutpoint (alpha-quantile)
 QQ-plot

det.res<-TRC(bushfirem,weights=bushfire.weights)
PlotMD(det.res$dist,ncol(bushfirem))
```

 POEM

Nearest Neighbour Imputation with Mahalanobis distance

Description

POEM takes into account missing values, outlier indicators, error indicators and sampling weights.

Usage

```
POEM(data, weights, outind, errors, missing.matrix, alpha = 0.5, beta = 0.5,
reweight.out = FALSE, c = 5, preliminary.mean.imputation = FALSE, monitor=FALSE)
```

Arguments

data a data frame or matrix with the data
 weights sampling weights
 outind an indicator vector for the outliers, 1 indicating outlier
 errors matrix of indicators for items which failed edits
 missing.matrix the missingness matrix can be given as input. Otherwise it will be recalculated
 alpha scalar giving the weight attributed to an item that is failing
 beta minimal overlap to accept a donor
 reweight.out if TRUE the outliers are redefined
 c tuning constant when redefining the outliers (cutoff for Mahalanobis distances)
 preliminary.mean.imputation
 assume the problematic observation is at the mean of good observations
 monitor if TRUE verbose output

Details

POEM assumes that an multivariate outlier detection has been carried out beforehand and assumes the result is summarized in the vectore outind. In addition further observations may have been flagged as failing edit-rules and this information is given in the vector error. The mean and covariance estimate is calculated with the good observations (not outliers and downweighted errors). Preliminary mean imputation is sometimes needed to avoid a non-positive definite covariance estimate at this stage. Preliminary mean imputation assumes that the problematic values of an observation (with errors, outliers or missing) can be replaced by the mean of the rest of the non-problematic observations. Note that the algorithm imputes these problematic observations afterwards and therefore the final covariance matrix with imputed data is not the same as the working covariance matrix (which may be based on preliminary mean imputation).

Value

Function winsimp returns a list whose first component output is a sub-list with the following components:

```

preliminary.mean.imputation
      logical. T if preliminary mean imputation should be used
completely.missing
      number of observations with no observed values
good.values      weighted number of of good values (not missing, not outlying, not erroneous)
nonoutliers.before
      number of nonoutliers before reweighting
weighted.nonoutliers.before
      weighted number of nonoutliers before reweighting
nonoutliers.after
      number of nonoutliers after reweighting
weighted.nonoutliers.after
      weighted number of nonoutliers after reweighting
old.center      coordinate means after weighting, before imputation
old.variances   coordinate variances after weighting, before imputation
new.center      coordinate means after weighting, after imputation
new.variances   coordinate variances after weighting, after imputation
covariance      covariance (of standardised observations) before imputation
imputed.observations
      indices of observations with imputed values
donors          indices of donors for imputed observations
new.outind      indices of new outliers
  
```

The further component returned by POEM is

```

imputed.data    Imputed data set.
  
```

Examples

```
data(bushfirem)
data(bushfire.weights)
outliers<-rep(0,nrow(bushfirem))
outliers[31:38]<-1
imp.res<-POEM(bushfirem,bushfire.weights,outliers,prel=TRUE)
print(imp.res$output)
var(imp.res$imputed.data)
```

sepe

Sample Environment Protection Expenditure Survey

Description

The sepe data set is a sample of the pilot survey in 1993 of the Swiss Federal Statistical Office on environment protection expenditures of Swiss private economy in the previous accounting year. The units are enterprises, the monetary variables are in thousand Swiss Francs (CHF). From the original sample a random subsample was chosen of which certain enterprises were excluded for confidentiality reasons. In addition, noise has been added to certain variables, and certain categories have been collapsed. The data set has missing values. The data set has first been prepared for the EU FP5 project EUREDIT and later been data protected for educational purposes.

Usage

```
data(sepe)
```

Format

A data frame with 675 observations on 23 variables.

idnr identifier (anonymous)

exp categoric variable: 1 = 'non-zero total expenditure', 2 = 'zero total expenditure', 3 = 'no answer to the question'

totinvwp total investment for water protection

totinvwm total investment for waste management

totinvap total investment for air protection

totinvnp total investment for noise protection

totinvot total investement for other environmental protection areas

totinvto overall total investment in all environmental protection areas

totexpwp total current expenditure in environmental protectiona area water protection

totexpwm total current expenditure in environmental protectiona area waste management

totexpap total current expenditure in environmental protectiona area air protection

`totexpnp` total current expenditure in environmental protection area noise protection
`totexpot` total current expenditure in other environmental protection area
`totexpto` overall total current expenditure in all environmental protection area
`subtot` total subsidies for environmental protection received
`rectot` total receipts from environmental protection
`employ` number of employees
`sizeclass` size class (according to number of employees)
`stratum` stratum number of sample design
`activity` code of economic activity (aggregated)
`popsiz` number of enterprises in the population-stratum
`popempl` number of employees in population activity group
`weight` sampling weight (for extrapolation to the population)

Details

The sample design is stratified random sampling with different sampling rates. Use package **survey** or **sampling** to obtain correct point and variance estimates. In addition a ratio estimator may be built using the variable `popempl` which gives the total employment per activity.

There are two balance rules: the subtotals of the investment variables should sum to `totinvto` and the expenditure subtotals should sum to `totexpto`.

The missing values stem from the survey itself. In the actual survey the missing values were declared as "guessed" rather than copied from records.

The sampling weight `weight` is adjusted for non-response in the stratum, i.e. `weight=popsiz/sampsiz`.

 TRC

Transformed rank correlations for multivariate outlier detection

Description

TRC starts from bivariate Spearman correlations and obtains a positive definite covariance matrix by back-transforming robust univariate medians and mads of the eigenspace. TRC can cope with missing values by a regression imputation using the a robust regression on the best predictor and it takes sampling weights into account.

Usage

```
TRC(data, weights, overlap = 3, mincor = 0, robust.regression = "rank",
    gamma = 0.5, prob.quantile = 0.75, alpha = 0.05, md.type = "m", monitor = FALSE)
```

Arguments

<code>data</code>	a data frame or matrix with the data
<code>weights</code>	sampling weights
<code>overlap</code>	minimum number of jointly observed values for calculating the rank correlation
<code>mincor</code>	minimal absolute correlation to impute
<code>robust.regression</code>	type of regression: "irls" is iteratively reweighted least squares M-estimator, "rank" is based on the rank correlations
<code>gamma</code>	minimal number of jointly observed values to impute
<code>prob.quantile</code>	if mads are 0 try this quantile of absolute deviations
<code>alpha</code>	(1-alpha) Quantile of F-distribution is used for cut-off
<code>md.type</code>	Type of Mahalanobis distance when missing values occur: "m" marginal (default), "c" conditional
<code>monitor</code>	if TRUE verbose output

Details

TRC is similar to a one-step OGK estimator where the starting covariances are obtained from rank correlations and an ad hoc missing value imputation plus weighting is provided.

Value

TRC returns a list whose first component output is a sublist with the following components:

<code>sample.size</code>	number of observations
<code>number.of.variables</code>	number of variables
<code>number.of.missing.items</code>	number of missing values
<code>significance.level</code>	1-alpha
<code>computation.time</code>	elapsed computation time
<code>medians</code>	componentwise medians
<code>mads</code>	componentwise mads
<code>center</code>	location estimate
<code>scatter</code>	covariance estimate
<code>robust.regression</code>	input parameter
<code>md.type</code>	input parameter
<code>cutpoint</code>	The default threshold MD-value for the cut-off of outliers

The further components returned by TRC are:

<code>outind</code>	Indicator of outliers
<code>dist</code>	Mahalanobis distances (with missing values)

BV'eguin, C., and Hulliger, B. (2004). Multivariate outlier detection in incomplete survey data: The epidemic algorithm and transformed rank correlations. *Journal of the Royal Statistical Society, A* 167(Part 2.), 275-294.

Examples

```
data(bushfire, bushfire.weights)
det.res <- TRC(bushfire, weights=bushfire.weights)
PlotMD(det.res$dist, ncol(bushfire))
print(det.res)
```

weighted.quantile	<i>Quantiles of a weighted cdf</i>
-------------------	------------------------------------

Description

A weighted cdf is calculated and quantiles are evaluated. Missing values are discarded.

Usage

```
weighted.quantile(x, w, prob = 0.5, plot = FALSE)
```

Arguments

x	vector of data
w	vector of (sampling) weights
prob	The probability for the quantile
plot	if TRUE the weighted cdf is plotted

Details

Weighted linear interpolation in case of non-unique inverse. Gives a warning when the contribution of the weight of the smallest observation to the total weight is larger than prob.

Value

The quantile for proportion prob.

Note

No variance calculation.

Author(s)

Beat Hulliger

See Also[svyquantile](#)**Examples**

```
x<-rnorm(100)
x[sample(1:100,20)]<-NA
w<-rchisq(100,2)
weighted.quantile(x,w,0.2,TRUE)
```

weighted.var

*Weighted univariate variance coping with missing values***Description**

This function is analogue to `weighted.mean`.

Usage

```
weighted.var(x, w, na.rm = FALSE)
```

Arguments

<code>x</code>	a vector with data
<code>w</code>	positive weights (may not have missings where <code>x</code> is observed)
<code>na.rm</code>	if TRUE remove missing values

Details

The weights w are standardised such that $\sum_{observed} w_i$ equals the number of observed values in x . The function calculates

$$\sum_{observed} w_i (x_i - weighted.mean(x, w, na.rm = T))^2 / ((\sum_{observed} w_i) - 1).$$

Value

The weighted variance of x with weights w (with missing values removed when `na.rm=TRUE`).

Beat Hulliger

See Also

See Also as [weighted.mean](#)

Examples

```
x<-rnorm(100)
x[sample(1:100,20)]<-NA
w<-rchisq(100,2)
weighted.var(x,w,na.rm=TRUE)
```

Winsimp

*Winsorization followed by imputation***Description**

Winsorisation of outliers according to the Mahalanobis distance followed by an imputation under the multivariate normal model. Only the outliers are winsorized. The Mahalanobis distance `MDmiss` allows for missing values.

Usage

```
Winsimp(data, center, scatter, outind, seed = 1000003)
```

Arguments

<code>data</code>	Data frame with the data
<code>center</code>	(Robust) estimate of the center (location) of the observations
<code>scatter</code>	(Robust) estimate of the scatter (covariance-matrix) of the observations
<code>outind</code>	Logical vector indicating outliers with 1 or TRUE for outliers
<code>seed</code>	Seed for random number generator

Details

It is assumed that `center`, `scatter` and `outind` stem from a multivariate outlier detection algorithm which produces robust estimates and which declares outliers observations with a large Mahalanobis distance. The cutpoint is calculated as the least (unsquared) Mahalanobis distance among the outliers. The winsorization reduces the weight of the outliers:

$$\hat{y}_i = \mu_R + (y_i - \mu_R) \cdot c/d_i$$

, where μ_R is the robust center and d_i is the (unsquared) Mahalanobis distance of observation i .

Value

Function `winsimp` returns a list whose first component output is a sub-list with the following components:

<code>cutpoint</code>	Cutpoint for outliers
<code>proc.time</code>	Processing time
<code>n.missing.before</code>	Number of missing values before
<code>n.missing.after</code>	Number of missing values after imputation

The further component returned by `winsimp` is

<code>imputed.data</code>	Imputed data set.
